December 19, 2019

Machine learning models: Support Vector Machines, Adaboosting, XGBoost and Linear Regression are applied to the chemical properties of the elemental make up of superconductors in order to predict the critical temperature. The $\sigma(T_c)$ found is $\pm$9.25K and R2 score 0.93. This is an improvement on the 2018 published paper modelling the same data.

I Introduction

Currently fossil fuels play a big role in our global economy, but will soon be finished. As we come to rely more and more on renewable sources of energy how will we transport energy efficiently. Society has an ever increasing desire for more energy, however the current grid cannot sustain this. The voltage and current that can be passed through overhead cables and pylons is limited; also approximately 10% of power travelling through the cables is dissipated as heat. Liquid hydrogen and superconductors offers a brilliant solution. Burning hydrogen is clean and produces no CO_2, the only by-product is water. A pipe made of superconducting material transporting liquid hydrogen would transport electricity without energy loss and transport fuel, the liquid hydrogen. Therefore, superconductors are essential for creating future smart grids. This paper looks at known superconductors with the aim of predicting their critical temperatures.

The theory of superconductivity is described briefly with an explanation to which features are likely to be most relevant for superconductivity. Next the methods of Adaboost and Support Vector Machines (SVM) are presented, although more methods are implemented in the report. Thirdly, the dataset and the pre-processing performed on the

data is explained. This report creates a benchmark by making predictions with linear regression and additionally uses bayesian optimisation, for finding the optimal hyperparameters for model training (Appendix VII.I). The results of linear regression, Adaboost, SVM and XGBoost are presented and discussed.

II Theory of Superconductors

A superconductor is a material which when cooled below the critical temperature, will conduct electricity without resistance and expel magnetic flux (usually critical temperature $T_c \leq 20\,\mathrm{K}$) [5]. Thus, electron currents can flow freely with no dissipation of energy.

The property of resistance free currents was first discovered by Heike Kamerlingh Onnes in 1911 from experiments with mercury (Hg), earning him a Nobel Prize [5]. In the following years a lot of research has focused on superconductors and their attributes.

In 1933, the Meissner effect was discovered [5]. In the superconducting state, a superconductor expels magnetic flux, behaving diamagnetically. From this, one can categorize superconductors into two types. Type I superconductors revert to a normal conductor in presence of a weak magnetic field above a certain threshold, $\mathrm{H_c}$ In contrast, type II superconductors have two critical magnetic fields, H_{c1} and H_{c2} [2] [5] . Upon reaching the first critical magnetic field, the normal and superconducting states co-exist; flux penetrates the superconductor in fluxoids [5]. Above the seconds critical magnetic field (H_{c1}) the superconductor becomes normal.

Superconductivity is a phenomenon which cannot be explained by perfect conductivity. Electrical resistance occurs due to impurities, grain boundaries and lattice vibration, which scatter conduction electrons [5]. In principle, a perfect conductor would be without these properties and conduct electricity without resistance. If a magnetic field is applied to a material and subsequently became a perfect conductor, any applied magnetic field would be screened by surface currents and the magnetic field within the perfect conductor is unchanged. In another scenario if material becomes perfect conducting in zero magnetic field, the perfect conductor would again oppose any change in magnetic flux to keep the flux inside equal to zero. This explains the fascinating properties of superconductivity: no matter the history of the material it will always expel magnetic flux.

So far, theory only explain low temperature superconductors well, while high temperature ones ($80\,\mathrm{K} \leq \mathrm{T_c}$ remains unaccounted for. John Bardeen, Leon Cooper and John Schrieffer laid the groundwork for today's understanding of low temperature superconductors, and were later awarded with the Nobel Prize in 1972 for the BCS-theory [5]. In short, they hypothesised that conducting electrons in a superconductor form "Cooper

pairs". Low-energy interactions with a negatively charged electron makes the positive ion-lattice move on a microscopic scale, attracting another electron in such a way that electrons meet no resistance [2]. At high temperatures, this interaction is broken by thermal energy.

As a consequence of superconductors' unique properties, new technological advancement and discoveries can be made. Superconductors have great potential for usage within energy-storage, computers, particle accelerators, motors, high sensitivity sensors and more.

III Methods

In this prediction analysis, different prediction models to predict the critical temperature of a known superconductor are used. First, two boosting variants, Adaboost and XGBoost (XGB) are introduced. Likewise, the support vector machines (SVM) are illuminated.
The the data set and its preparation is described in section III.IV. Finally, the linear regression benchmark model is introduced.
All implementations can be found in `https://github.com/lasse-steinnes/Machine_Learning_Project3`.

III.I Adaboost

Adaboost is an iterative method using an ensemble of weak regressors or weak classifier. After each iteration the fitting is an improvement of the previous iteration. This improvement comes from re-weighting the training data based upon the mistakes of the weak-regressor or weak-classifier; larger weights are given to mis-classified data, or bigger MSE for the regression case.

In this report, the Adaboost is implemented following the explanations from H. Drucker [6], which is a modification of `Adaboost.R` from Y. Freund and R. Schapire [7]. The Adaboost is implemented as follows:

In the function `AdaBoost.training`, firstly the weights are initialised equal to 1 for each sample.

$$w_i = 1 \quad and \quad i = 1, 2, ..., N$$

The probability of each sample in the training data is:

$$p_i = \frac{w_i}{\sum_{i=1}^{N} w_i}$$

The training data is then fitted to a decision tree. The weights are passed to the sklearn decision tree function using the parameter `sample_weights`. A prediction is then made using the (weighted) decision tree on the test sample. The training loss is found from a particular loss function: linear, square law or exponential. For example in the square loss function:

$$L_i = \frac{(y_i^p - y_i)^2}{argmax(y_i^p - y_i)^2}$$

where w_i^p is the prediction and y_i is the training data. The average loss $\bar{L}$ is calculated by multiplying the individual losses with their respective probability and making a summation.

$$\bar{L} = \sum_{i=1}^{N} L_i p_i$$

The parameter β is defined as:

$$\beta = \frac{\bar{L}}{1 - \bar{L}}$$

The parameter α is defined as:

$$\alpha = log \frac{1.0}{\beta}$$

which will be used later in making the ensemble prediction.

The weights are then updated using β and the loss L_i.

$$w_i = w_i \beta^{1-L_i}$$

The current iteration is now finished and the weights w_i are fed into the next iteration. The predictions, decision trees, α and β are stored after each iteration.

Once all the iterations are completed, the function `AdaBoost.evaluate` is run. This function calculates the ensemble prediction. Firstly all the predictions are stacked to-

gether in a matrix.

$$\begin{bmatrix} y_0^1 & y_0^2 & y_0^3 & y_0^4 & y_0^5 & y_0^6 & \cdots & y_0^M \\ y_1^1 & y_1^2 & y_1^3 & y_1^4 & y_1^5 & y_1^6 & \cdots & y_1^M \\ y_2^1 & y_2^2 & y_2^3 & y_2^4 & y_2^5 & y_2^6 & \cdots & y_2^M \\ y_3^1 & y_3^2 & y_3^3 & y_3^4 & y_3^5 & y_3^6 & \cdots & y_3^M \\ y_4^1 & y_4^2 & y_4^3 & y_4^4 & y_4^5 & y_4^6 & \cdots & y_4^M \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ y_N^1 & y_N^2 & y_N^3 & y_N^4 & y_N^5 & y_N^6 & \cdots & y_N^M \end{bmatrix}$$

where N is the number of samples in the prediction and M is the number of iterations. Each column represents the predictions from one iteration of the Adaboost.

Next, the predictions are put in ascending order. For example, the prediction of the 0th sample from iteration 5 (y_0^5) could have a value less than the prediction from iteration 1 (y_0^1) and hence need to be ordered. An example is shown below if there are 5 samples and 6 iterations of the adaboost. In reality within the code, it is a matrix of the indices which are put in ascending order.

$$\begin{bmatrix} y_0^5 & < y_0^6 & < y_0^2 & < y_0^3 & < y_0^4 & < y_0^1 \\ y_1^2 & < y_1^6 & < y_1^5 & < y_1^3 & < y_1^4 & < y_1^1 \\ y_2^1 & < y_2^6 & < y_2^2 & < y_2^3 & < y_2^5 & < y_2^4 \\ y_3^5 & < y_3^1 & < y_3^2 & < y_3^3 & < y_3^4 & < y_3^6 \\ y_4^4 & < y_4^5 & < y_4^3 & < y_4^1 & < y_4^2 & < y_4^6 \end{bmatrix}$$

Using the matrix of indices from above the parameters α are ordered, leading to a matrix as follows:

$$\begin{bmatrix} \alpha^5 & \alpha^6 & \alpha^2 & \alpha^3 & \alpha^4 & \alpha^1 \\ \alpha^2 & \alpha^6 & \alpha^5 & \alpha^3 & \alpha^4 & \alpha^1 \\ \alpha^1 & \alpha^6 & \alpha^2 & \alpha^3 & \alpha^5 & \alpha^4 \\ \alpha^5 & \alpha^1 & \alpha^2 & \alpha^3 & \alpha^4 & \alpha^6 \\ \alpha^4 & \alpha^5 & \alpha^3 & \alpha^1 & \alpha^2 & \alpha^6 \end{bmatrix}$$

Next, a cumulative matrix is created of the one above. Hence, the last element in each row is the sum of all α. The index of the median value in each row indicates the index of the ensemble prediction. In the first row for example, if $\alpha^5 + \alpha^6 + \alpha^2$ is equal or greater than the median, then index 2 (y_0^2) is the ensemble prediction for the 0th sample. Doing the same for each sample results in the ensemble prediction for the data set.

It should be noted that literature on Adaboosting for the regression case are not well written. The authors of this report found difficulty understanding content from [6] and [7] due to the poor and sometimes complicated explanations.

III.II XGBoost

XGBoost like Adaboost is an iterative method which improves at each iteration of the model, but uses a gradient descent method. The XGBoost is optimised for speed and performance and constructs decision trees in parallel. The paper by T. Chen and C. Guestrin introduces the XGBoost [3].

In this paper, XGBoost's hyperparameters are tuned sequentially with 5-fold cross validation using sklearn's `GridSearchCV` in the program `XGBregressiongrid.py`, following the guidelines described by A. Jain [1]. The hyperparameters, their significance for the model and the range tested in grid search is given in tab. 1. The grid search is run with 4 parallel threads (nthread: 4) and "reg:squarederror" as objective.

Table 1: **XGBoost hyperparameters**: An overview of the hyperparameters of XGBoost tuned in this paper, using sklearn's `GridCV`. More details about the XGBRegressor can be found in [15].

Hyperparameter	Description	Gridsearch range
η	Boosting learning rate	$[0.03, 0.05, 0.07, 0.1, 0.2, 0.3]$
γ	Min. loss reduction to make partition	$[0.0, 0.1, 0.2, 0.3, 0.4]$
reg α	L1 regularization term on weights	$[0.0, 0.0001, 0.001, 0.005, 0.01, 0.05, 0.1]$
reg λ	L2 regularization term on weights	$[0.0, 0.0001, 0.001, 0.005, 0.01, 0.05, 0.1]$
max depth	Maximum tree depth	$[4, 5, 6, 7, 8, 9, 10]$
mean child weight	Min. sum of instance weight needed in child	$[1, 2, 4]$
subsample	Subsample ratio of the training instance	$[0.7, 0.8, 0.9]$
colsample by tree	Subsample ratio of columns for each tree	$[0.7, 0.8, 0.9]$
n estimators	Number of trees	$[100, 150, 200, 250, 300, 350, 400, 500]$

The best hyperparameters from the grid search is then run on the program `XGB_regression.py`, calling the weak regressor method in class `Regression` in `methods.py`. A nested 5-fold cross-validation is performed, followed by extraction of predicted T_c, MSE and R2-scores, also plotting predicted T_c vs. actual T_c, together with feature importance.

The program is run with `importance type = 'gain'` and `importance type = 'weight'` from the weak regressor method. In that way, feature importance can later be extracted from the table of information. Gain describes "the average gain across all splits the feature is used in", while weight is "the number of times a feature is used to split the data across all trees" [15].

III.III Support-Vector Machines

Data points in a p-dimensional space that can be separated by a surface in the p-1 dimensional affine subspace - a hyperplane - are well suited for statistical learning using support vector machines (SVMs). SVMs are widely used for classification, but are also applicable to solving regression problems, which uses similar properties as the classifier. The methods explained for classification is based on M. Jensen's lecture notes [14], while the regression part is inspired by Hastie's book on Machine Learning [8].

For a matrix $\mathbf{X}$ with dimension n $\times$ p, where n is the number of observations and p the number of features, the hyperplane of row vector $\mathbf{x}_i$ is

$$f(\mathbf{x}_i) = \mathbf{w}^T \mathbf{x}_i + b = 0. \tag{1}$$

In the above equation $\mathbf{w}$ represent the weights and b is the intercept. Any vector $\mathbf{x}_i$ that does not satisfy the above expression either lies above or below the hyperplane. In problems of two classes, f($\mathbf{x}$) > 0 and f($\mathbf{x}$) < 0 can be used to separate datapoints into their respective category.

Any two points on the hyperplane must satisfy

$$\mathbf{w}^T (\mathbf{x}_i - \mathbf{x}_j) = 0, \tag{2}$$

thus the distance to a point $\mathbf{x}$ from the hyperplane will be

$$\delta = \frac{1}{||\mathbf{w}||}(\mathbf{w}^T \mathbf{x} + b) = 0. \tag{3}$$

Instead of defining a cost-function with a set of all misclassified points and doing a gradient descent optimization, the standard way of optimizing SVMs is through defining a margin M, and maximizing the margin distance using Lagrangian multipliers, λ.

The margin must satisfy the condition

$$\frac{1}{||\mathbf{w}||} y_i(\mathbf{w}^T \mathbf{x}_i + b) \geq M \; \forall i = 1, 2, ..., n. \tag{4}$$

By scaling $||\mathbf{w}|| = 1/M$, one can find the maximum M by minimizing $||\mathbf{w}|| = \mathbf{w}^T \mathbf{w}$ while upholding eq. 4. To find an extremal value a function f (df = 0) which variables are under constraints ϕ_k, the following equation must hold

$$\frac{\partial f}{\partial x_i} + \sum_k \lambda_k \frac{\partial \phi_k}{\partial x_i} = 0 \tag{5}$$

The Lagrangian loss-function is then defined as

$$\mathscr{L} = \sum_i \lambda_i - \frac{1}{2} \sum_{ij}^{n} \lambda_i \lambda_j y_i y_j \mathbf{x_i}^T \mathbf{x_j}, \tag{6}$$

when $\lambda_i \geq 0$ and $\sum_i \lambda_i y_i = 0$. In addition, the Karush-Kuhn-Tucker condition must be met, as it generalizes the Lagrangian multipliers method to include inequality constraints,

$$\lambda_i (y_i (\mathbf{w}^T \mathbf{x}_i + b) - 1) \ \forall i \tag{7}$$

If $\lambda_i > 0$, then $y_i(\mathbf{w}^T \mathbf{x}_i + b) = 1$ and the vector $\mathbf{x}_i$ is on the boundary, being a support vector defining the margin M. When $\mathbf{x}_i$ is not on the boundary, $\lambda_i = 0$. Minimizing 6 with respect to λ, the problem reduces to

$$min_\lambda \frac{1}{2} \lambda^T \mathbf{P} \lambda + \mathbf{q}^T \lambda, \tag{8}$$

subject to

$$\mathbf{G}\lambda \preceq \mathbf{h} \wedge \mathbf{A}\lambda = f. \tag{9}$$

In the above equations $P_{ij} = y_i y_j K(\mathbf{x}_i \mathbf{x}_j)$, where the kernel (K) is the transformation for non-linear classification (i.e. basis functions), and $\mathbf{G}$ is a matrix collecting all inequalities, while $\mathbf{A}$ describes the equality constraints. To read more in detail about this convex optimalization problem, see Jensen's notes on the subject [14]. Finding λ_i under these constraints results in the following weights and intercept of the hyperplane

$$\mathbf{w} = \sum_i \lambda_i y_i \mathbf{x}_i \tag{10}$$

$$b = \frac{1}{y_i} - \mathbf{w}^T \mathbf{x}_i. \tag{11}$$

Thus any observations $\mathbf{x}_i$ can be classified by

$$y_i = sign(\mathbf{w}^T \mathbf{x}_i + b) \tag{12}$$

While modelling the behavior of complex datasets, working with hard margins would be unpractical, since the model should be able to predict unseen data. Thus, an error-insensitive - or soft- classifier is practical in this regard. The slack variable $\xi = (\xi_1, ..., \xi_n)$ introduce an error term on the margin, so that

$$y_i(\mathbf{w}^T \mathbf{x}_i + b) = 1 - \xi_i, \tag{13}$$

where $\xi_i \geq 0$. The sum over all ξ_i's gives information about the total violation, and by selecting a value C, this error can be bounded. Misclassification will then occur when $\xi_i > 1$. Introducing $\xi_\mathbf{i}$ gives a new expression for the loss-functions and modified conditions to be met (see citation).

The regression case builds on a similar logic to that of classification. For simplicity, lets say we have linear regression where $f(x) = x^T\beta + \beta_0$, which can be generalized to non-linear models using kernels. In this case, estimating β entails minimizing

$$\sum_{i=1}^{N} V(y_i - f(x_i)) + \frac{\lambda}{2}||\beta||^2, \tag{14}$$

where

$$V_\varepsilon(r) = \begin{cases} 0 & \text{if} |r| < \varepsilon \\ |r| - \varepsilon, & \text{otherwise.} \end{cases} \tag{15}$$

For positive values of parameters $\widehat{\alpha}_i$ and $\widehat{\alpha}_i^*$, the optimization problem becomes

$$\min_{\widehat{\alpha}_i, \widehat{\alpha}_i^*} \varepsilon \sum_{i=1}^{N} (\widehat{\alpha}_i + \widehat{\alpha}_i^*) - \sum_{i=1}^{N} y_i(\widehat{\alpha}_i - \widehat{\alpha}_i^*) + \frac{1}{2} \sum_{i,j=1}^{N} (\widehat{\alpha}_i - \widehat{\alpha}_i^*)(\widehat{\alpha}_j - \widehat{\alpha}_j^*) \langle x_i, x_j \rangle . \tag{16}$$

Here $\langle x_i, x_j \rangle$ is the inner product, λ is a regularization parameter and ε is a parameter of the loss function. Eq. 16 is subject to the constraints

$$0 \leq \widehat{\alpha}_i,\ \widehat{\alpha}_i^* \leq 1/\lambda, \tag{17}$$

$$\sum_{i=1}^{N} (\widehat{\alpha}_i - \widehat{\alpha}_i^*) = 0, \tag{18}$$

$$\widehat{\alpha}_i \widehat{\alpha}_i^* = 0. \tag{19}$$

Under these constraints, it can be proven that the solution is

$$\widehat{\beta} = \sum_{i=1}^{N} (\widehat{\alpha}_i - \widehat{\alpha}_i^*) x_i \tag{20}$$

$$\widehat{f}(x) = \sum_{i=1}^{N} (\widehat{\alpha}_i - \widehat{\alpha}_i^*) \langle x_i, x_j \rangle + \beta_0. \tag{21}$$

In this way, only data points with non-zero $(\widehat{\alpha}_i - \widehat{\alpha}_i^*)$ will contribute to the regression, and are therefore called support vectors.

In this paper, SVM regression is used to predict T_c in the program `SVM_regression.py`, performing a nested 5-fold cross validation in the search for best slack parameter ε and cost-penalty λ (tab. 2). It uses the `svm` in the regression class, and returns statistical features of the model, specificly MSE and R2-scores, which is stored together with hyperparameters in a table of information. It also plots the weights and predicted T_c vs. actual T_c.

Table 2: **Hyperparameter values in model optimization**: A 5-fold nested cross-validation is performed with the following values for ε, which defines the margin and λ, the cost-penalty of the model.

Hyper parameter	range
ε	$[0.1, 0.01, 0.001, 0.0001, 1e-05]$
λ	$[10, 100, 1000, 10000, 100000, 1, 0.4, 0.04, 0.004, 0.0004,$ 0.1, 0.01, 0.001, 0.0001, 1e-05, 1e-06, 0.2, 0.02, 0.002, 0.0002, 2e-05, 2e-06, 0.4, 0.04, 0.004, 0.0004, 4e-05, 4e-06, 0.60, 4e-05, 4e-06, 0.6, 0.06, 0.006, 0.00060, 6.0e-05, 6e-06]

III.IV Data Set

The data set contains 21264 samples of known superconductors with each 80 features. The data set can be found in [11]. The distribution of critical temperatures is illustrated in figure 1. The main group of targets is at low temperature, i.e. most likely type I superconductors. A smaller group of super conductors is around 80 K, which probably are type II superconductors.

The 80 features are constructed from the following eight atomic properties of the constituent elements of the superconductor: Atomic mass, first ionization energy (energy to remove one valence electron, `fie`), atomic radius, density (at standard temperature and

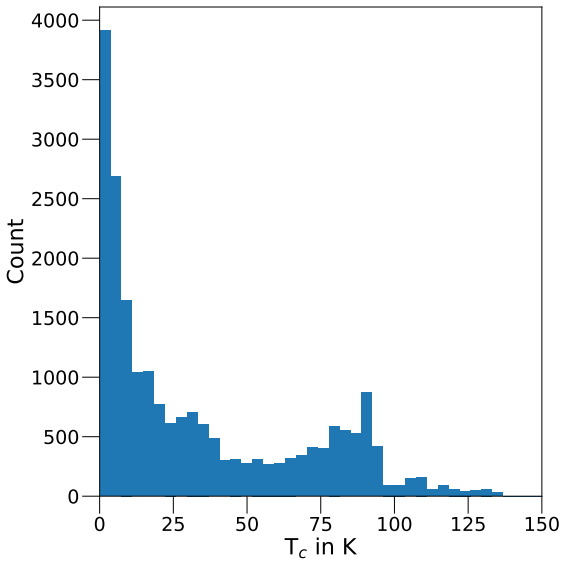

Figure 1: **Distribution of T_c**: The distribution of the target values in the regression.

pressure), electronic affinity (energy required to add electron to neutral element), fusion heat (or latent heat of fusion, i.e. energy to change from solid to liquid phase), thermal conductivity and the number of valence electrons.
From these features ten different averages and deviations are extracted. More details on the eight basic features and how to construct all 80 features is found in [9].

From the theory of superconductivity it is believed that several of the features in this dataset are important predictors. BCS theory describes the interaction between cooper pais by the phonon-electron interation; phonons are mediators. This means that poor conductors, with more phonons, are likely to be better superconductors than good conductors. Secondly, due to the experimentally found isotope effect in superconductors, the atomic mass influences critical temperature. As

$$M^{\alpha} T_c = \text{constant} \tag{22}$$

where α is a constant and M is the isotopic mass. This equation shows that by changing the isotope mass the critical temperature changes to keep the right hand side constant.

The critical temperature is separated into the target vector $\boldsymbol{y}$, while the design matrix $\boldsymbol{X}$ contains the 80 features. The design matrix is scaled such that the mean in each column is zero and the standard deviation of the column is one. This is done with `StandardScaler` from `sklearn.preprocessing`. The target values are mapped between [0,1] by setting $\tilde{\boldsymbol{y}} = \boldsymbol{y}/y_{\max}$ as new target values. The value of $y_{\max}$ is stored. This

allows for a back transformation to real temperatures.
Finally, the samples are shuffled and a column of ones might be added to the design matrix at the beginning.

III.V Linear Regression

Three different types of linear regression are used: ordinary least square (OLS), Ridge and LASSO regression. The functionality of `sklearn.linear_model` is used. 10-fold cross-validation determines the best linear regression model and the average results of the regression model. Because Ridge and LASSO regression have a regularization parameter λ, a nested 10-fold-5-fold cross-validation is used. The inner (5-fold) cross-validation splits again the training data from the outer (10-fold) cross-validation. From the model's performance on the inner test data the optimal λ is picked. The model's performance are then again tested on the outer test data set (evaluation data set). These results are quoted.

In order to find the best λ two search strategies are used: A plain grid-search or a Bayesian optimization. The plain grid-search tests the model on $\lambda = n \times 10^{-m} \leq 1$, where $n = \{1,2,4,6,8\}$ and $m = \{0,1,2,3,4,5,6\}$. The Bayesian optimization searches for the optimal λ in the interval [0,1] by maximizing $-MSE$ of the model on the inner test data set. Possible λ values are sampled randomly. 50 initial guesses and 50 updates of the Bayesian model are performed, before the best λ is returned on the current fold. In order to account for the randomness of the sampling, in each fold 10 bootstraps are performed on top. More details on the Bayesian optimization is found in appendix VII.I.

IV Results

The results of the various models from the previous section are presented. First, in section IV.I, an in-depth analysis of the hyperparameter tuning with grid search and Bayesian optimization is perforemed on the linear regression benchmark models.
Then, in the following sections, results of the SVM and boosting models are shown.

IV.I Linear Regression

The results of the cross-validation are listed in tab. 3. OLS seems to give the overall best model with an R2 score of 0.755 and an uncertainty on the critical temperature $\sigma(T_c) = \sqrt{MSE} y_{\max} = \pm 16.90\,\mathrm{K}$. Contrary, the average $\sigma(T_c) = \pm(17.61 \pm 0.41)\mathrm{K}$ is the same as found in [9] for linear regression. The uncertainty on the average is related to the standard deviation of the MSE in different folds (with the same regularization strength if ap-

Table 3: **Results of Linear Regression**: The results of 10-fold cross-validation are presented. The regularization parameter λ in Ridge and LASSO regression are tuned with a nested cross-validation with 10-folds and 5-folds. For Bayesian optimization 10 bootstraps are applied within each nested cross-validation.
The model performance is measured on a part of the data set which was not used for training or λ selection.

Model	Search		λ	MSE	R2	unc. T_c in K
OLS		best		0.00835	0.755	16.90
		mean		0.00907 ± 0.00043	0.735 ± 0.011	17.61 ± 0.41
Ridge	Grid	best	1E-6	0.00888	0.74	17.45
		mean	1E-6	0.00908 ± 0.00042	0.735 ± 0.011	17.63 ± 0.40
	Bayes	best	0.031	0.00918	0.7369	17.72
		mean	0.015 ± 0.015	0.00908 ± 0.00041	0.7351 ± 0.0073	17.63 ± 0.23
LASSO	Grid	best	1E-6	0.008882	0.7373	17.436
		mean	1E-6	0.009005 ± 0.000066	0.7372 ± 0.0017	17.555 ± 0.064
	Bayes	best	9.0E-6	0.0092	0.737	17.73
		mean	0.0005 ± 0.0016	0.00956 ± 0.00084	0.721 ± 0.023	18.07 ± 0.75

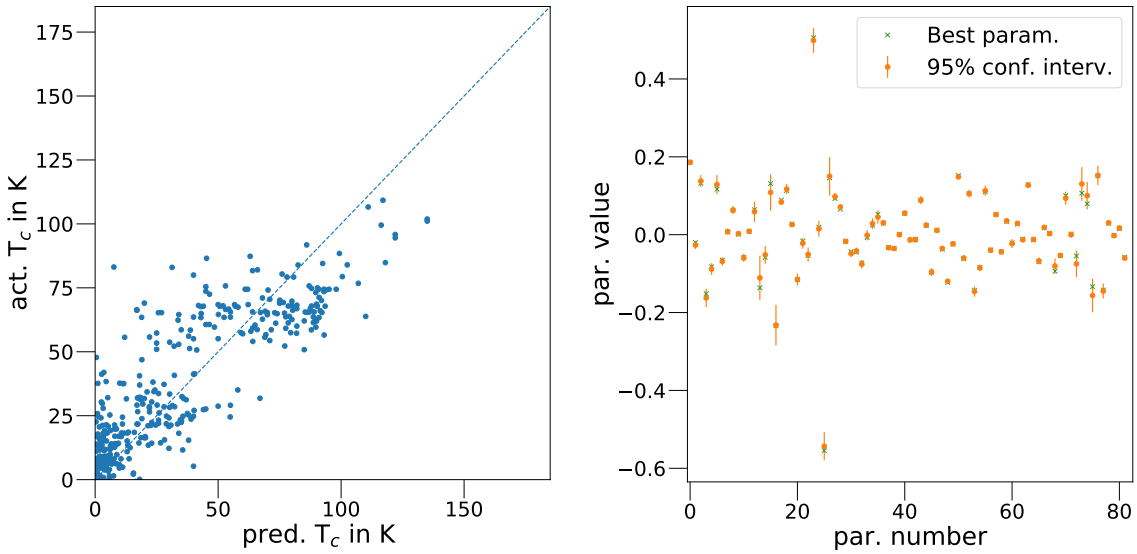
plicable). In other words, it measures the variability of the expected critical temperature uncertainty of the models prediction.

The best model will have a uncertainty on the critical temperature as small as and a minimal variability of it. Therefore, the best linear regression model is LASSO regression with $\lambda = 10^{-6}$ with $\sigma(T_c) = \pm(17.555 \pm 0.064)$K. The best LASSO regression has then an R2-score of 0.7373 and $\sigma(T_c) = 17.436$ K. The prediction of the model and the respective parameters are shown in Fig. 2.

Grid-search and Bayesian optimization based search give not the same results as can seen in tab. 3, but the MSE curve based on both searches coincide as Fig. 3 demonstrates. The Bayesian optimization search is more nosy due to the random nature of the sampling of λ but also more centered around a region of minimal MSE.

Based on the largest absolute parameters, the most important features are determined. Consistently, for all types of linear regression the most important parameters are `entropy_fie`, `wtd_mean_atomic_radius` and `wtd_gmean_atomic_radius` sorted from third most important to most important[1]. Therefor, the most important constituents features are atomic radius and first ionization energy.

[1] `wtd` means weighted, `gmean` is the geometric mean; more details on construction are found in [9].



(a) Model prediction

(b) Model parameters

Figure 2: **Best Linear Regression Model**: From tab. 3 the model with the average least T_c uncertainty is picked. This is the LASSO regression with $\lambda = 10^{-6}$. The prediction from the model is plotted against the true critical temperature in figure (a) for randomly selected sample points. In figure (b) the model parameter values are shown. The three parameters with the largest absolute value are `entropy_fie`, `wtd_mean_atomic_radius` and `wtd_gmean_atomic_radius`. They are sorted from importance rank 3 to 1, where 1 is the most important feature.

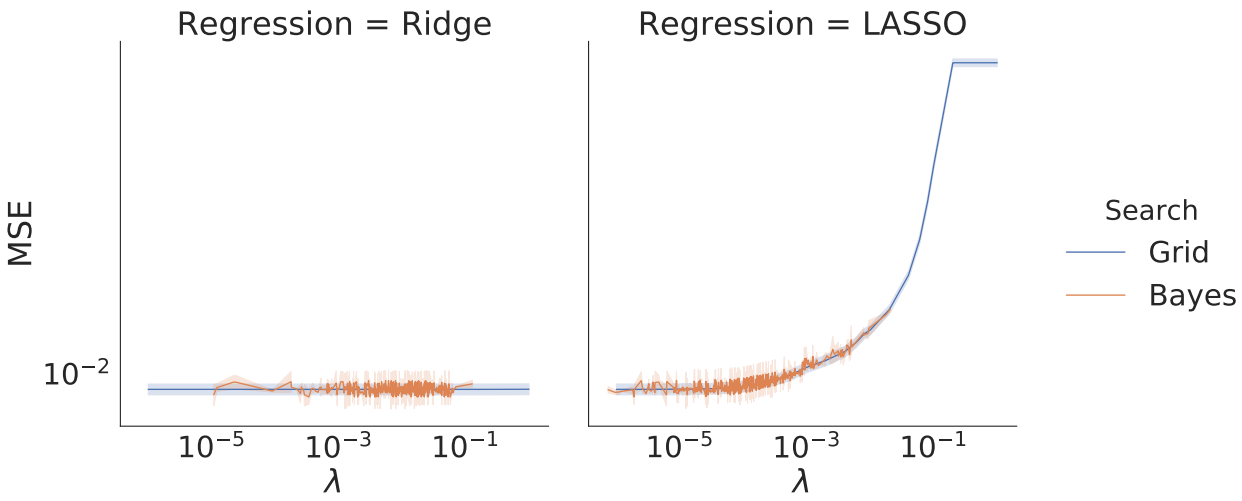


Figure 3: **Regularization Parameter Search**: Compared are the two search strategies which are used to find the best regularization parameter λ in Ridge and LASSO regression.

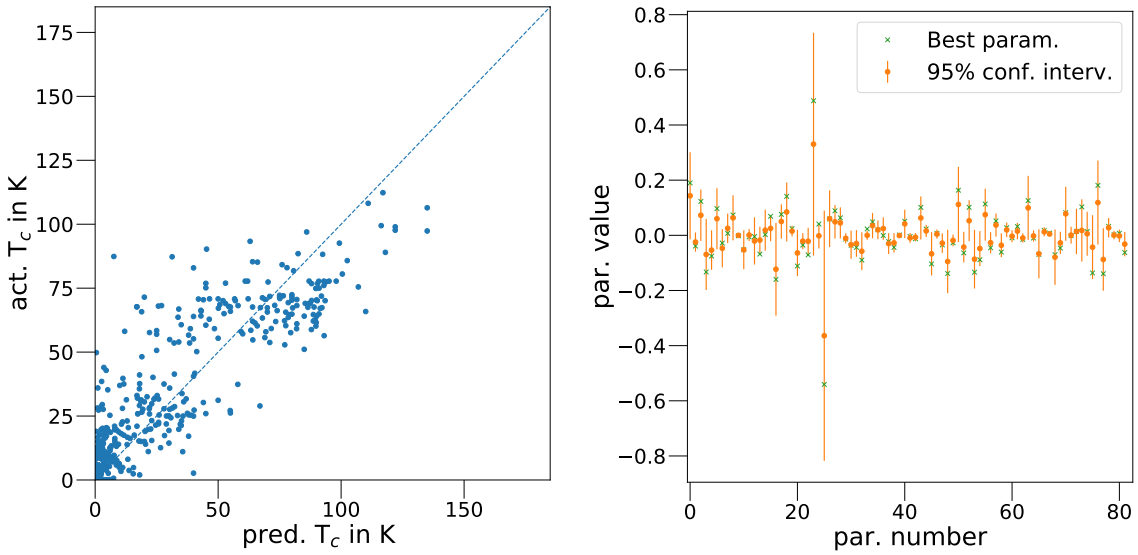
IV.II Support-Vector Machines

The results of 5-fold cross validation are shown in tab. 4. The best model has an uncertainty $\sigma(T_c) = 18.06$, with $\varepsilon = 0.1 > \lambda = 0.06$. As with linear regression, adding a cost-penalty enhances model performance.

The predicted T_c and actual T_c is presented in Fig. 4, together with the most important weights. The results suggest having a larger margin than cost-penalty is necessary for best model performance, due to clustering and outliers in the actual T_c.



(a) Model prediction

(b) Model parameters

Figure 4: **Best Support-Vector Machine Model**: The best model performance for SVM, with hyper parameters as described in tab. 4. **a)** Predicted critical temperature (T_c) plotted against true critical temperature (T_c). **b)** The weights of the model with confidence intervals. The three weights with highest absolute values, the most important for model performance, are `wtd_gmean_atomic_radius`, `wtd_mean_atomic_radius` and `const`. (ie. bias) (high-low).

Table 4: **Results of Support-Vector Machine**: The results of a nested 5-fold cross-validation are presented. The results in the table are from out-of-sample set which is unused in the parameter search. ε defines the margin and λ is the cost-penalty of the model.

Search	ε	λ	MSE	R2	unc. T_c in K
Best	0.1	0.06	0.00954	0.724	18.06
Mean	0.1	0.06	0.00924 ± 0.00024	0.730 ± 0.009	17.78 ± 0.23

IV.III Adaboosting

The results of 10-fold cross validation are shown in tab. 5. The best overall model has an R2 score of 0.93 and an uncertainty in the critical temperature $\sigma(T_c) = \sqrt{MSE} y_{max} = \pm 9.252\,\mathrm{K}$. This is a better result than in [9]. There does appear to be over-fitting as the

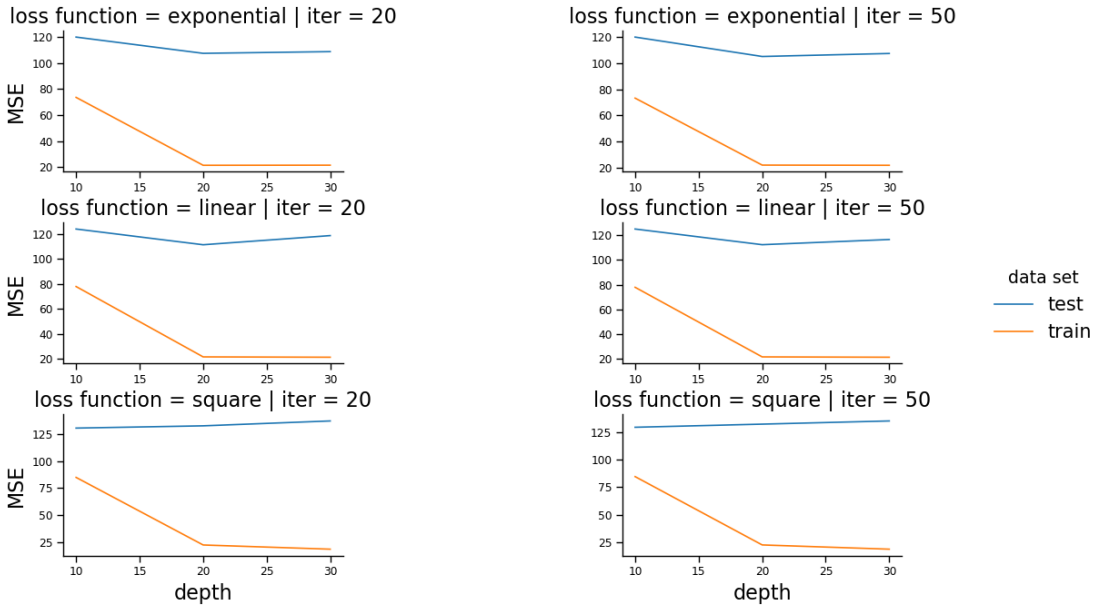


Figure 5: **Test Train Plots:** MSE as a function of decision tree max depth for varied hyper-parameters. Results are 10-fold cross validated.

training MSE is very low in comparison to the test MSE. On the other hand the model does predict well on out of sample data.

Initially it was believed that adaboosting with a weak decision tree of maxdepth = 1 (the weakest possible) would most appropriate as most sources state to start with a regressor/classifier no better than guessing. However, it was found that increasing the max depth of the decision tree to approximately 15 improved the MSE and R2 score on the test and evaluation set. Fig. 5 shows the results of test and train MSE and how they are moving apart as a function of depth.

An example of the hyper-parameter search can be seen in Fig. 8. The predicted critical temperature as a function of the actual critical temperature is plotted in Fig. 6. The same hyper-parameters are used to fit using the sklearn Adaboost (Fig. 7).

Table 5: **Results of Adaboost**: The results of 10-fold cross-validation are presented. The results in the table are from out-of-sample set which is unused in the parameter search. The sklearn implementation was not run with a GridSearch for best hyper-parameters; the hyper-parameters from the own implementation are used and then sklearn predicts using these hyper-parameters.

Model	Depth	Loss function	no. iterations	MSE in K^2	rMSE in K	R2
Own Adaboost	15	exponential	50	85.595	9.252	0.93
Sklearn Adaboost	15	exponential	50	98.568	9.928	0.92

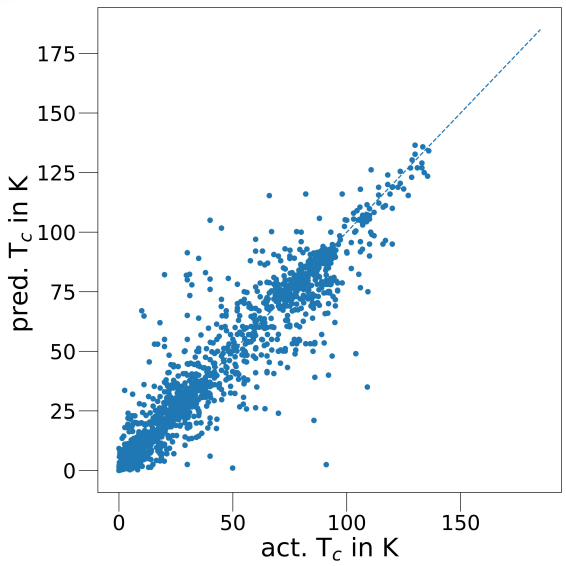

Figure 6: **Best Adaboost:** Predicted critical temperature as a function of actual critical temperature. A line y = x is plotted to show ideal result. Prediction is on out-of-sample data. The MSE is 85.595 K^2 and R2 score 0.93.

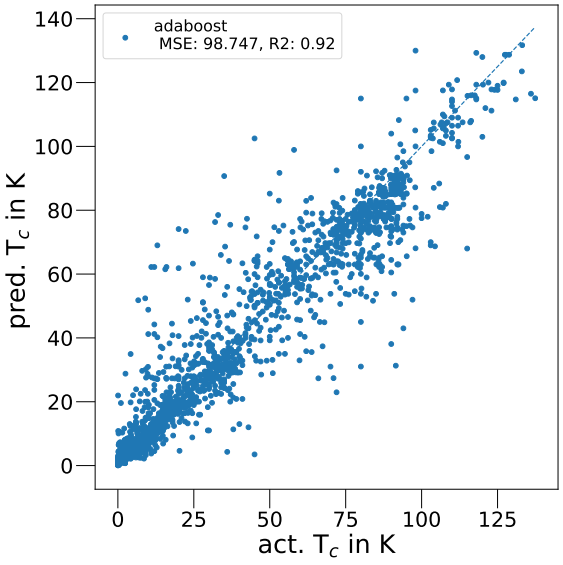

Figure 7: **Sklearn Adaboost:** Predicted critical temperature as a function of actual critical temperature.

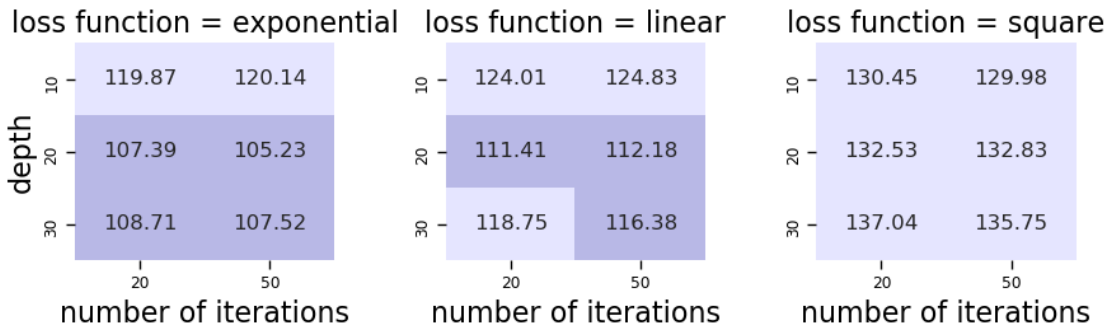

Figure 8: **Hyper-parameter Search:** Grid of heatmaps showing the test MSE of a parameter search. Results are 10 fold cross-validated. The lowest test MSE ($105.23\,\mathrm{K}^2$) in the figure results from the exponential loss function, a depth of 20 nodes and 50 iterations.

IV.IV XGBoost

A grid search is performed with 9 different hyperparameters (see tab. 1) with 5-fold cross validation. Results for the best model is shown in tab. 6. The uncertainty $\sigma(T_c) = 10.37$, which a higher uncertainty than in [9].

Table 6: **Results of XGBoost**: The results of 10-fold cross-validation are presented. The results in the table are from out-of-sample set which is unused in the parameter search. First, hyper parameters were tuned with 5-fold cross validation using sklearn's `GridCV`, and then a program was run to get statistics for the best parameters. Optimal parameters not shown in table: γ: 0.0, λ: 0.0, min child weight: 2, subsample: 0.8, col sample by tree: 0.8.

Search	n tress	max depth	η	α	MSE	R2	unc. T_c in K
Best	200	9	0.1	0.001	0.00314	0.9090	10.37
Mean	200	9	0.1	0.001	0.00311 ± 0.00015	0.9091 ± 0.0049	10.32 ± 0.25

The best model prediction of T_c is plotted against actual T_c in Fig. 9. This prediction is a result of the feature importance of the weights and gain presented in Fig. 10. Note that importance differ between feature type.

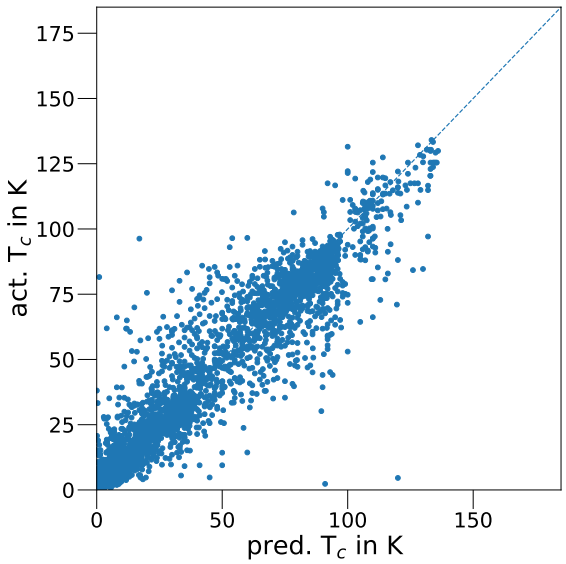

Figure 9: **Best XGBoost Model:** Predicted critical temperature as a function of actual critical temperature after 5-fold CV with best hyperparameters described in tab. 6.

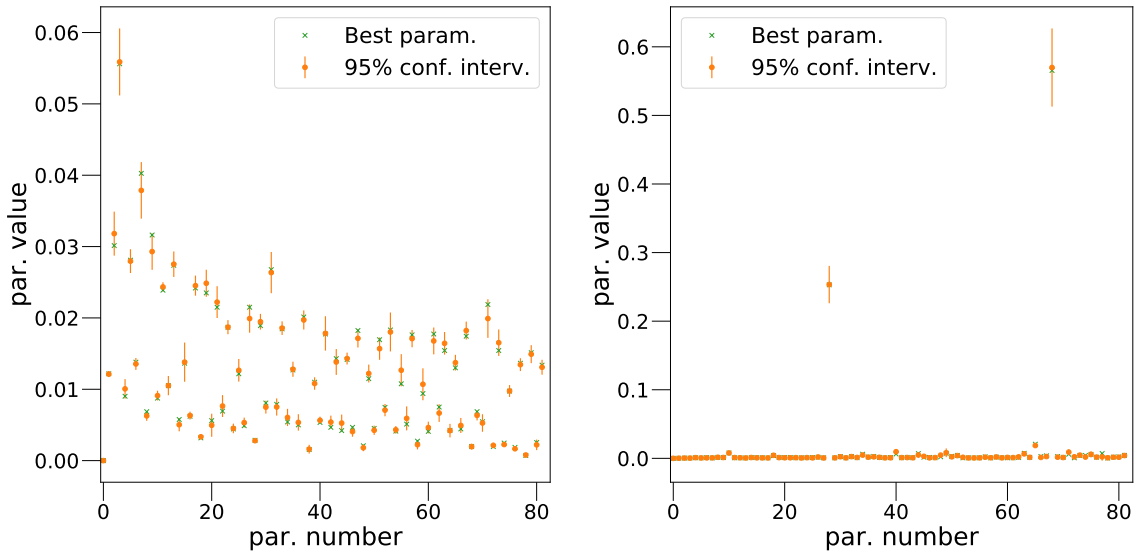

(a) Importance: Weights

(b) Importance: Gain

Figure 10: **Importance of parameters in XGBoost**: Importance of parameters for the best model, as described in tab. 6.**a)** Importance of weights. The most important weights are (high-low) `wtd_mean_atomic_mass`, `wtd_entropy_atomic_mass` and `mean_atomic_mass`. **b)** Importance of gain. The most important gain for model prediction are (high-low) `range_ThermalConductivity`, `range_atomic_radius`, `wtd_gmean_ThermalConductivity`.

V Discussion

The obtained results from the previous section are discussed and compared with [9]. First, the necessity of Bayesian optimization is discussed in section V.I. Likewise, the other results are compared to the paper [9] and finally, in section V.III, it is tried to interpret the results in the context of BCS-theory.
In general, results from [9] are reproduced and a slight improvement in the model uncertainty with Adaboosting is observed compared to the best model uncertainty in [9]. This is closer discussed in section V.II.

V.I Bayesian Optimization

The usage of Bayesian optimization to tune the regularization parameter λ in Ridge and LASSO regression is not paying of. The grid search gives faster and better results.

Figure 3 might give a hint why this is. The grid search (blue) gives a smooth curve of $MSE(\lambda)$. This is due to the interpolation between the sampled grid points, which have a stepsize large enough to not resolve the full detail of $MSE(\lambda)$. The sampling from the

Bayesian optimization reveals the rugged structure of $MSE(\lambda)$. Obviously, $MSE(\lambda)$ is sensitive to small changes in λ. Such small changes lead to wildly varying MSE values. This makes it hard for the Gaussian process to capture the function $MSE(\lambda)$. Maybe with more updates, the result would be better. The question is, if this approach to Bayesian

optimization, with random sampling, initial guesses, absolute number of updates and fixed exploration parameter, can handle well such noisy functions. Maybe substituting random sampling for the initial guesses with a grid search might give the Gaussian process model a better chance modeling the average function behavior.The number of updates could be also tied to an abortion criteria, like n-rounds of no improvement. Last,

but not least, the exploration parameter ξ could vary throughout the updating process, i.e. decaying from a large value to a smaller value. This might lead to a better exploration of the search space in the beginning and then narrowing down towards a most likely maxima.

Overall, Bayesian optimization has the potential to search higher dimensional hyperparameter spaces more efficiently than brute-force grid search. However, in addition to defining the search space, Bayesian optimization introduces at least three more hyperparameter, initial guesses, number of updates and exploration parameter. This list does not include, that the surrogate function and acquisition function itself are subject to many input parameters and options. The user must carefully evaluate if the Bayesian optimiza-

tion introduces unnecessary complexity to the hyperparameter search or if it might be a promising efficiency improvement. In the case of linear regression, a plain grid search is sufficiently fast and gives good results. Therefore, Bayesian optimization is not needed for this kind of problem.

V.II Model Performance

The benchmark prediction is set by LASSO-regression with a $\sigma(T_c) = \pm 17.56\,\mathrm{K}$. This is comparable to the benchmark in [9]. The linear SVM performs not better nor worse than the linear regression models. Those models should not be used for gerneral prediction of T_c.

The Adaboost model implemented in this report achieves an rMSE ($\sigma(T_c)$) of 9.25 K compared to 9.5 K in [9] using XGBoost. These results are found using 10-fold cross validation with one set held out as a final evaluation set. The achieved result of $\sigma(T_c) = \pm 9.2\,\mathrm{K}$

is predicted from the evaluation set. To improve on this an inner cross-validation could have been used to ensure each fold has an opportunity of being the evaluation set.

The XGBoost model trained in this analysis performs slightly worse than [9]. Multiple reasons could cause this. First, the grid search. The used grid is not exactly the same as used in [9]. This illustrates again the problem with hyperparameter searching discussed in the previous section. Maybe a random search or Bayesian optimization would lead to better or at least to reproducible results. Due to lack of time such searches are not performed. Another reason might be the different cross-validation technique.

V.III Physical Interpretation

In BCS-theory, the electron lattice interaction results in Cooper-pairs below the critical temperature. This study focuses on the constituent elements of the lattice and tries to predict critical temperature directly from the single element properties. Linear models,

such ad all linear regressions and SVM, yield a moderately good R2 score around 0.73 and a uncertainty around $\pm 17.6\,\mathrm{K}$. From figures 2(a) and 4(a), one can see, that for high temperature superconductors ($T_c \approx 80\,\mathrm{K}$) the spread of the prediction is larger than for low temperature superconductors ($T_c \leq 20\,\mathrm{K}$). This might be a hint, that high temperature superconductivity is not linearly dependant on element properties.

A closer look into the most important features for linear models reveal that the basic property on which linear model predict is the atomic radius (figure 2(b) and 4(b)). The third most important parameter is not as pronounced as the first two, but nonetheless it is the first ionization energy of the valence electron in all linear models. Physically, the atomic radius influences the lattice spacing via the bond-length [4]. This, in turn affects the phonons of the lattice which are the driving part in Cooper-pair formation in BCS-theory for low temperature superconductors.

A closer investigation into the superconductors for which the predicted critical temperature is more than averagely far away from the true critical temperature could illuminate more properties of high temperature superconductors.

The first ionization energy, might influence the band-structure of the lattice or at least is highly correlated with electronic properties of the solid. This might influence superconductivity because usually poor conductors are often superconductors.

The non-linear boosting models perform far better than the linear models. The R2 is around 0.9 and the best uncertainty on the predicted critical temperature is $\pm 9.3\,\mathrm{K}$. Moreover, the spread from the true value is more or less uniform with temperature (figure 6

and 9). This means, that the model includes a more accurate representation of superconductivity based on constituent properties of the solid. From the XGB it is known, that the important properties are thermal conductivity, atomic radius and atomic mass. For the Adaboost, it was not possible to extract most important parameters at this point.

The reoccurrence of the atomic radius emphasize the the importance already found in linear models. More interestingly is the thermal conductivity. It is itself a property of solids depending on many factors among which are phonons, lattice structure (Deby) and electronic conductivity (Wiedmann-Franz-law). It might incapsulate more complex relationship between solid features and superconductivity than in BCS-theory is described.

While the element features based on thermal conductivity and atomic radius are pronounced in the gain of the XGB model, the atomic mass is important in the XGB weights. Arguably, the information about importance of a feature is encoded in the gain of XGB. Nonetheless, it might be interesting to note that the atomic weight feature drives the importance in the weights because it might be related to the isotope effect in equation (22).

VI Conclusion

This study can reproduce the findings of [9] and partially improve results. For known superconductors the critical temperature can be predicted with an uncertainty from the square root of the MSE $\pm 9.25\,\mathrm{K}$ which is a slight reduction in uncertainty of 3%.
The models prediction is most importantly based on the superconductor constituents features of atomic radius and thermal conductivity. Those features can be related to BCS-theory for low temperature superconductivity. Moreover, they might give a hint on properties important to high temperature superconductivity.

The findings might be interesting for the theory of superconductivity in two ways: First, the found compound features might give hints how a complete theory of superconductivity could look like and what material properties are important. Second, superconductors where the models significantly fail, i.e. more than one square-root MSE deviation between predicted and actual critical temperature, might display interesting properties. A future research into those outlier might reveal new phenomena in superconductivity or give rise to new classifications of superconductors.

An other future extension of the machine learning models could be to combine classification of superconducting and normal conducting materials and, if applied, the prediction of the critical temperature. Not only could such a model give more hints for a complete theory of superconductivity, but also open new possibilities in application. For example, such a complex model could be used to focus material research on potential supercon-

ductors based on constituent features and anticipated critical temperature.

VII Appendix

VII.I Bayesian Optimization

One fundamental problem with grid-search based hyperparameter optimization is, that the model to optimize is only evaluated on predefined grid points. If the search wants a higher resolution, usually the step size between suggested hyperparameter values is decreased. However, this becomes quickly computationally expensive if the model needs to be evaluated on many grid points. Moreover, uninteresting regions are also sampled at the same frequency as interesting regions of hyperparameter space. This is a waste of computation power.

One possible solution is to use Bayesian optimization techniques. The main idea is to use Bayes theorem to optimize a scalar function $f = f(d)$ given some data d

$$p(f|d) \propto p(d|f)p(f). \tag{23}$$

In Bayesian statistic terminology $p(f|d)$ is the posterior probability of a function value f given the data d, $p(d|f)$ the likelihood of the d given f and $p(f)$ is the prior probability of f [10]. With out loss of generality, it is assumed that f is to maximize.

The goal is now to estimate the posterior probability with an surrogate function S. This is often done by using Gaussian processes (GP) [12] to fit the data d, because GP's are fast to evaluate, fast to fit and give an estimation of model uncertainty. After each evaluation of the function f the GP model is updated to the new data.

With the help of an acquisition function A, a new data point is selected based on the surrogate function. This involves suggesting a number of data point candidates d_i to the surrogate function and take its prediction $\mu(d_i)$ for f and its uncertainty $\sigma(d_i)$ into the acquisition function. Then select the data point candidate which maximizes A. Then evaluate the the model on this data point and update S.

In this paper, the expected improvement [13] is used as the acquisition function

$$A = EI(d_i) = (\mu(d_i) - f_{\max} - \xi)\mathbf{\Phi}(Z(d_i)) + \sigma(d_i)\phi(Z(d_i)). \tag{24}$$

$\mathbf{\Phi}$ and ϕ are the cumulative distribution and the probability density function of a normal distribution, respectively. The value of $Z(d_i)$ is defined as

$$Z(d_i) = \frac{\mu(d_i) - f_{\max} - \xi}{\sigma(d_i) + \varepsilon}, \tag{25}$$

where $f_{\max}$ is the current maximal function value, $\varepsilon = 10^{-9}$ is a small constant chosen to avoid division by zero and ξ is the exploration parameter usually set to 0.01.

The first part of the sum in eq. (24) describes regions where the GP model predicts large values for the function f. The second part of the sum is related to regions with large GP uncertainty. ξ then regulates if regions of higher uncertainty (large ξ) or regions of high value predictions of GP model for f (small ξ).
To sum up, in algorithm 1 all the relevant steps are collected.

To illustrate the outcome (and test the implementation of the Bayesian maximization), a simple 1-dimensional optimization is performed. The used function is

$$f(x) = x^2 \sin(5\pi x)^6$$

with additional Gaussian noise ($\mu = 0,\ \sigma = 0.05$). The results of the Bayesian maximization can be seen in figure 11. 50 initial guesses and 50 updates are used. The GP model does not quiet capture the function f. However, from the histogram one can see, that most of the points at which f is evaluated are near the maximum of f. The found $x_{\max}$ is close to the true $\hat{x}_{\max}$. Differences are due to the noise on f and the random nature of the algorithm.

In order to use Bayesian maximization on hyperparameter tuning of a regression model, a few changes are made to f:

$$f \to -MSE(\boldsymbol{X}, \boldsymbol{y}|\boldsymbol{\lambda}) \tag{26}$$

In other words, the negative mean squared error MSE of the regression model $r(\boldsymbol{X}, \boldsymbol{\lambda})$, depending on the input data $\boldsymbol{X}$ and the set of hyperparameters $\boldsymbol{\lambda}$, and the target values $\boldsymbol{y}$ is maximized with respect to $\boldsymbol{\lambda}$.

Algorithm 1 Bayesian Maximization: The basic outline for a Bayesian optimization algorithm. Inputs are the function to optimize f, the search space D and the exploration parameter ξ

function BAYESMAX(f, D, ξ)
  $\boldsymbol{d}$, $\boldsymbol{f}_i \leftarrow [\,], [\,]$ ▷ Initialize data d and evaluated function values f_i
  for # init. samples **do** ▷ Initial guesses
    $d_g \leftarrow \text{random}(D)$ ▷ Draw a random point from search space
    $\boldsymbol{d}$, $\boldsymbol{f}_i \leftarrow \boldsymbol{d}.\text{append}(d_g)$, $\boldsymbol{f}_i.\text{append}(f(d_g))$
  end for
  $GP \leftarrow \text{GaussianProcess.fit}(d,\ f_i)$ ▷ Initalize GP
  $d_{\max}$, $f_{\max} \leftarrow \text{argmax}(\boldsymbol{f}_i)$, $\max(\boldsymbol{f}_i)$
  for # updates **do** ▷ Bayesian Optimization
    $\boldsymbol{d}_i$, $\boldsymbol{EI} \leftarrow [\,], [\,]$
    for # tries **do** ▷ Find next point d_g to evaluate f
      $d_t \leftarrow \text{random}(D)$
      $\mu(d_t),\ \sigma(d_t) \leftarrow GP(d_t)$ ▷ Evaluate GP at suggested point d_t
      $\boldsymbol{d}_i$, $\boldsymbol{EI} \leftarrow \boldsymbol{d}_i.\text{append}(d_t)$, $\boldsymbol{EI}.\text{append}(EI(d_t))$ ▷ Use eq. (24)
    end for
    $d_g \leftarrow \text{argmax}(\boldsymbol{EI})$ ▷ Suggest point with maximal EI
    $\boldsymbol{d}$, $\boldsymbol{f}_i \leftarrow \boldsymbol{d}.\text{append}(d_g)$, $\boldsymbol{f}_i.\text{append}(f(d_g))$ ▷ Evaluate f at suggested point d_g
    $d_{\max}$, $f_{\max} \leftarrow \text{argmax}(\boldsymbol{f}_i)$, $\max(\boldsymbol{f}_i)$
    $GP \leftarrow GP.\text{fit}(d,\ f_i)$ ▷ Update GP
  end for
  return $d_{\max}$, $f_{\max}$
end function

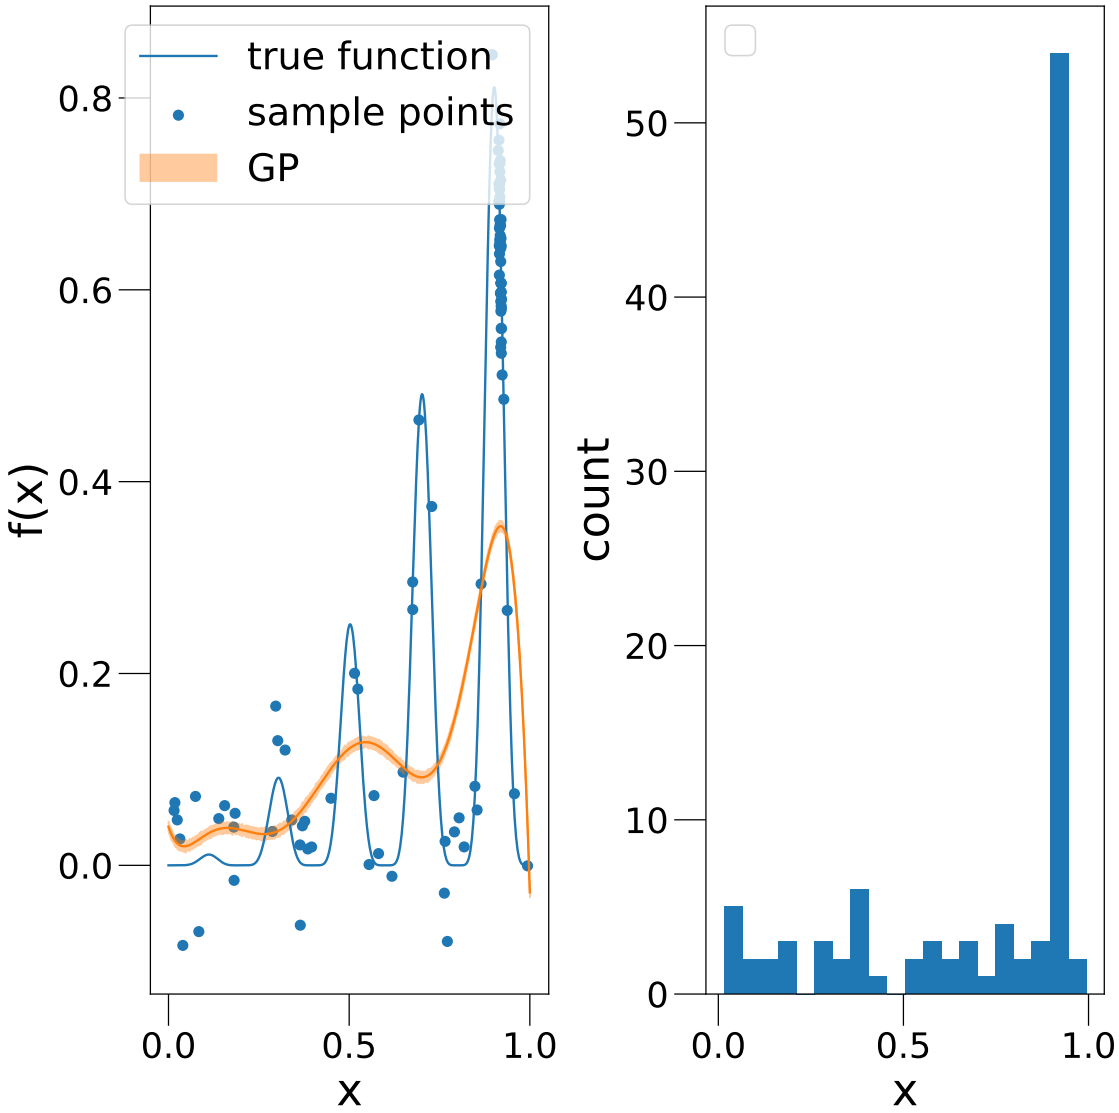

Figure 11: **1D Bayesian Maximization**: To test functionality, this 1D toy example is used. The goal is to find x which maximizes $f(x)$. The band around the curve of the Gaussian process (GP) illustrates the uncertainty of the GP model at this point.
